A series of MgB<sub>2</sub> thin films systematically disordered by neutron irradiation have been studied by Scanning Tunneling Spectroscopy. The c-axis orientation of the films allowed a reliable determination of local density of state of the  $\pi$  band. With increasing disorder, the conductance peak moves towards higher voltages and becomes lower and broader, indicating a monotonic increase of the  $\pi$  gap and of the broadening parameter. These results are discussed in the frame of two-band superconductivity.

The discovery of two gap superconductivity in MgB<sub>2</sub> [1, 2] has renewed the interest on this mechanism that was theoretically predicted since the fifties. This peculiar feature occurs in MgB<sub>2</sub> because of the presence of two sets of bands which cross the Fermi level. The larger gap ( $\Delta_{\sigma} \sim 7 \text{ meV}$ ) is related to the  $\sigma$  bands, originated by  $p_{xy}$  B orbitals, strongly interacting with phonons, and characterized by a bidimensional Fermi surface; the smaller gap  $(\Delta_{\pi} \sim$ 2 meV) is related to the  $\pi$  bands originated by  $p_z$  B orbitals and having an isotropic Fermi surface. Two band models predict that non-magnetic scattering causes pair breaking as magnetic one does in a one band superconductor;[3] this is a unique effect of interband scattering, because mixing  $\sigma$  and  $\pi$  Cooper's pairs causes a complete isotropization of the entire Fermi surface. In the strong interband scattering limit, the two gaps should merge to one when the critical temperature  $(T_c)$  drops to the isotropic value of about 20-25 K.[4, 5] To verify these predictions, several efforts have been made to evaluate the energy gaps in samples where defects were introduced by different techniques such as substitutions (Al [6, 7, 8] or C [9, 10, 11, 12]), irradiation [13, 14] or in films grown naturally disordered [15] Due to the possible simultaneous occurrence of several sources of disorder, a quantitative evidence of the role of the interband scattering has not yet been given. In particular, substitution may induce extrinsic effects related to charge doping, structural instability and inhomogeneous distribution of impurities. However, it is widely accepted that the  $\Delta_{\pi}$  value is weakly affected by disorder while  $\Delta_{\sigma}$  decreases linearly with  $T_c$ , and recently the merging of the gap has been observed in irradiated samples at a critical temperature (11 K) lower than the predicted one.[14]

In this paper, we report on Scanning Tunneling Spectroscopy (STS) measurements on c-oriented thin films where the defects were systematically introduced by neutron irradiation. Neutron irradiation introduces neither charge doping nor electronic or structural instabilities; furthermore, in thin films it guarantees a uniform distribution of defects in the entire sample. [16] STS directly probes the Local Density of States (LDOS), whose broadening can be analyzed in connection with scattering mechanisms induced by irradiation.

MgB<sub>2</sub> thin films (2000 Å thick) were grown at The Pennsylvania State University by Hybrid Physical Chemical Vapor Deposition (HPCVD) on 5x5 mm<sup>2</sup> SiC substrates. Details about the samples fabrication and their basic characterization can be found in Ref. 17. Neutron irradiation was carried out at the spallation neutron source SINQ of Paul Sherrer Institut in Villigen (Zurich). Each film was sealed under vacuum in a small quartz ampoule just after deposition; this setup allowed to perform irradiation also for long times without compromising samples quality. Several samples (Samples IRR10, IRR30, IRR35, and IRR40 in the following) have been irradiated at thermal neutron fluences ranging from 6.4·10<sup>15</sup> to 9.5·10<sup>18</sup> cm<sup>-2</sup>. A description of the damage mechanism, as well as detailed structural, transport and magnetic characterization were reported elsewhere.[16] Low temperature STS experiments were performed in a cryogenic system able to operate at variable temperature and in magnetic field, using a PtIr home-made tip. The films were mounted on a Scanning Tunneling Microscope scanning head in inert helium atmosphere to preserve the surface quality.

Table I reports the main features of the measured samples: as the fluence increases,  $T_c$  value changes from 41 K to 17 K, and the residual resistivity  $\rho_0$  varies by two orders of magnitude.

TABLE I: Main properties of the measured irradiated films.

Sample	Neutron Fluence (cm <sup>-2</sup> )	$T_c(K)$	$\rho_0 \; (\mu \Omega \cdot \text{cm})$
IRR10	$6.4 \cdot 10^{15}$	41.05	1.2
IRR30	$7.7 \cdot 10^{17}$	36.1	18
IRR35	$3.0 \cdot 10^{18}$	22.2	52
IRR40	$9.5 \cdot 10^{18}$	17.0	87

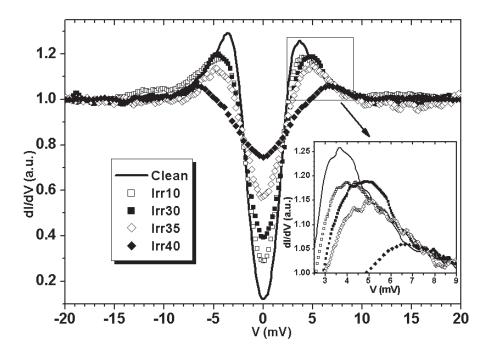

FIG. 1: STS spectra, at T = 4.2 K, on the irradiated measured MgB<sub>2</sub> films. Measurements parameters: tunnel current: 100 pA; bias voltage: 20 mV. A spectrum on a clean sample, from Ref. 15, is also reported as reference.

Figure 1 shows the typical normalized tunneling conductance STS spectra for neutron irradiated films of different fluences. All the spectra were collected through a standard lock-in technique and were acquired (at T=4.2 K) by stabilizing the feedback loop with a tunnel current of 100 pA and a bias voltage of 20 mV. The STS spectra on each sample were reproducible from point to point on the sample surface, and they overlapped when normalized by changing the tunnel resistance. This assures that we were measuring in pure tunneling regime and guarantees a reduced role of possible contaminated surface layers. STS measurements were performed only when such conditions were achieved. A spectrum on a non irradiated film ( $T_c = 41 \text{ K}$ , from Ref. 15), measured in the same conditions, is also reported as reference.

The plot reveals a clear monotone trend of the spectra. As  $T_c$  decreases, with increasing neutron fluences, the zero-bias conductance (ZBC) increases and the coherence superconductivity peaks shift to higher voltages and appear less pronounced. This behavior is more clearly shown in the inset to Fig. 1. Only one-peak spectra were found on all the samples. Because in c-axis oriented films the current is injected parallel to the c-axis, the  $\pi$  band contribution is dominant in the tunneling spectra as compared to the  $\sigma$  band contribution.[18] Therefore, we identify the observed peaks as corresponding to the  $\pi$  gap,  $\Delta_{\pi}$ .

The increase of the ZBC is likely due to a broadening of the superconducting LDOS, as a consequence of the increasing disorder, which introduces subgap states and smears the LDOS divergence. The displacement of the peaks towards higher energies could be ascribed mainly to two effects: the LDOS broadening, supported by the simultaneous decrease in the peak height, and an intrinsic change of the  $\Delta_{\pi}$  value as disorder increases and T<sub>c</sub> decreases.

Measurements in magnetic field perpendicular to the films surface were also performed. Figure 2 reports the ZBC as a function of the applied field for some samples. The plot shows that the most irradiated samples are much less sensitive to the magnetic field, as already observed in differently disordered samples. [15] This result will be discussed in detail elsewhere.

To get further information on the evolution of LDOS as a function of irradiation induced disorder, a quantitative

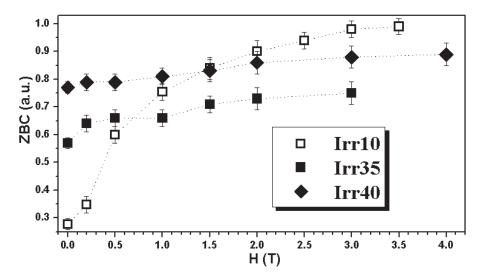

FIG. 2: Zero Bias Conductance as a function of the applied magnetic field (perpendicular to the surface) for samples Irr10, Irr35, Irr40.

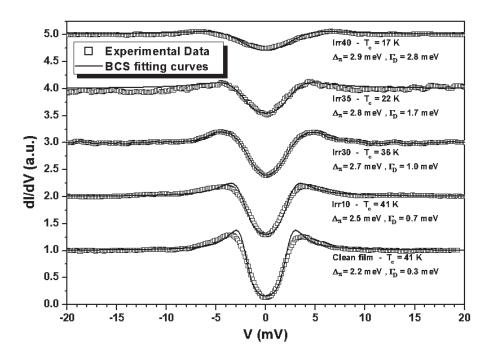

FIG. 3: STS spectra, at T=4.2 K, on the irradiated measured MgB<sub>2</sub> films; fitting curves, evaluated by a BCS one-gap model, are superimposed to the experimental data. Plots are vertically shifted for clarity.

analysis can be developed. As a first approximation, we fitted the measured dI/dV spectra through a simple (single gap) BCS model with a phenomenological Dynes parameter  $\Gamma_D$ .[19] In fact, when only the  $\pi$  band gives a significant contribution to the tunnel current, the two-band calculation for MgB<sub>2</sub> approaches a simple one-band BCS model,[18] with  $\Delta_{\pi}$  and  $\Gamma_D$  as fitting parameters. The  $\Gamma_D$  parameter includes all the measured broadening on the superconducting LDOS, due to intrinsic, pair-breaking, effects, but also to extrinsic effects such as thermal noise. The results of the best fit curves and fitting parameters are shown in Fig. 3.

The good agreement between the fits and data in Fig. 3 confirms the adequacy of the one-band model. Although the high  $\Gamma_D$  value estimated for the lowest  $T_c$  sample seriously affects the quantitative reliability of the simple model, it furnishes anyway an indication of the film behavior. The use of a two band model, with the estimated  $\sigma$  gap from the specific heat data on bulk samples irradiated through the same technique,[14] does not change the extracted  $\pi$  gap value substantially, but introduces more free parameters, making the overall analysis less straightforward and clear.

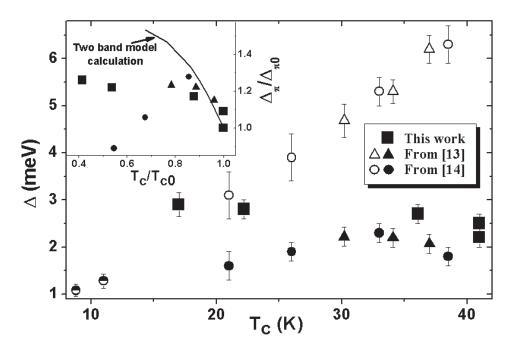

FIG. 4:  $\Delta_{\pi}$  values evaluated by STS spectra as a function of  $T_c$  (squares). For comparison,  $\Delta_{\pi}$  and  $\Delta_{\sigma}$  evaluated by specific heat measurements on neutron irradiated polycrystalline samples (triangles, from Ref. 13, and circles, from Ref. 14) are also reported. In the inset,  $\Delta_{\pi}/\Delta_{\pi0}$  vs.  $T_c/T_{c0}$  is plotted together with a theoretical calculation.

Figure 4 shows  $\Delta_{\pi}$  values as a function of  $T_c$  measured from our STS spectra.  $\Delta_{\sigma}$  and  $\Delta_{\pi}$  evaluated by specific heat measurements on neutron irradiated polycrystalline samples [13, 14] are also plotted for comparison. The  $\Delta_{\pi}$  values estimated by STS are usually reported to be larger than those estimated by specific heat. This accounts for the slightly different  $\Delta_{\pi}$  values obtained by the different measurements for the lightly irradiated samples. The  $\Delta_{\pi}$  value estimated by STS, even considering the error bars, clearly increases as  $T_c$  decreases. In heavily irradiated thin films ( $T_c = 22$  and 17 K), the extracted  $\Delta_{\pi}$  value from the STS spectra are close to  $\Delta_{\sigma}$  estimated by specific heat.

The increase of  $\Delta_{\pi}$  is predicted by the two-band model for increasing interband scattering.[3, 20] Up to now, an experimental proof of this effect is lacking due to the difficulty to introduce disorder in a controlled way without simultaneous doping effects. With the reliable gap data from the neutron irradiated samples a comparison with the theory is possible. In the inset to Fig. 4,  $\Delta_{\pi}/\Delta_{\pi 0}$  data as a function of  $T_c/T_{c0}$  from this work and from Refs. 13 and 14 are shown, where  $\Delta_{\pi 0}$  and  $T_{c0}$  are the  $\pi$  gap and the  $T_c$  values of the unirradiated samples, respectively. The solid line represents the theoretical prediction of the two band model for increasing interband scattering.[20] For  $T_c/T_{c0}$  ranging from 1 to 0.85 ( $\Delta T_c = T_{c0}T_c \sim 6$  K), all the three data series show a similar increase of  $\Delta_{\pi}/\Delta_{\pi 0}$  in agreement with the theoretical curve. This suggests that for low levels of disorder the main mechanism of  $T_c$  reduction is the pair breaking due to interband scattering. In the regime of small interband scattering, the scattering rate,  $\Gamma_{inter}$ , can be calculated as [21]  $\Delta T_c/T_{c0} = 0.2\Gamma_{inter}/k_BT_{c0}$ ; with  $\Delta T_c = 6$  K we estimate  $\Gamma_{inter} \sim 2.5$  meV.

For  $T_c/T_{c0}$ ; 0.85 the experimental data do not agree; the  $\Delta_{\pi}/\Delta_{\pi 0}$  values of this work are nearly constant and those from the specific heat on bulk samples decrease with decreasing  $T_c$ . In both cases, the data remain below the theoretical curve that continues to increase. Thus for these levels of disorder other mechanisms cause the decreasing of  $\Delta_{\pi}$ , and consequently the suppression of the  $T_c$ . Also for strong interband scattering  $\sigma$  and  $\pi$  Cooper pairs are expected to mix, but the single-gap model used to extract  $\Delta_{\pi}$  considers only the  $\pi$  contribution. Not surprisingly, for the sample with  $T_c$ =17 K we found that  $2\Delta_{\pi}/k_BT_c = 3.9$ , which is too high for the  $\pi$  band but reasonable for the  $\sigma$  band.

In Fig. 5 the estimated Dynes broadening parameter  $\Gamma_D$  is reported as a function of  $\rho_0$ . It increases linearly with  $\rho_0$  from 0.3 to 2.8 meV. This linear correlation seems to suggest that quasiparticle relaxation processes, which affect  $\rho_0$ , could enhance pair breaking mechanisms which influence  $\Gamma_D$ . A linear increase of  $\Gamma_D$  with resistivity was first observed and discussed in Ref. 22, which suggested that finite lifetime effects due to inelastic electron-electron scattering vary linearly with resistivity, being enhanced by disorder. In a two gap superconductor, in principle both intraband and interband events can contribute to the observed scattering processes, which cannot be sorted out from the present data. However, the intraband relaxation rate,  $\Gamma_{intra}$ , can be roughly estimated by  $\rho_0$  assuming equal intraband relaxation rate in  $\sigma$  and  $\pi$  bands.[23] It ranges from 0.1 to 0.6 eV (see upper scale in Fig. 5), much higher than  $\Gamma_D$ . Interestingly  $\Gamma_D$  values are close to  $\Gamma_{inter}$ . For example, the sample with  $\Gamma_c = 36$ K has  $\Gamma_{inter} \sim 1.6$ meV

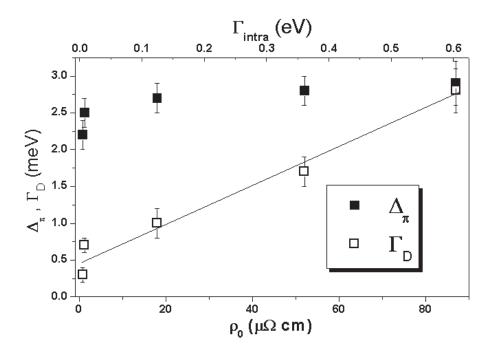

FIG. 5:  $\Delta_{\pi}$  and  $\Gamma_{D}$  values estimated by tunnel spectra as a function or residual resistivity  $\rho_{0}$  (lower scale). On the upper x-scale, the intraband scattering  $\Gamma_{intra}$  has been plotted, estimated as in Ref. 23 in the hypothesis of equal relaxation rate in  $\sigma$  and  $\pi$  bands. The continuous line is only a guide for eyes.

and  $\Gamma_D = 1$ meV. We believe that this agreement is not fortuitous. Indeed, in a two gap superconductor the interband scattering is expected to cause pair breaking as scattering with magnetic impurities does in single gap superconductor; therefore, it is reasonable that the interband scattering can strongly influence the broadening of the tunnel LDOS of the  $\pi$  band. Furthermore, this framework implies a linear dependence between interband and intraband scattering rates (suggested by the linear dependence of  $\Gamma_D$  on  $\rho_0$ , as discussed above) as both mechanisms scale with the defect density, which increases with the neutron fluence. Since the extrapolated low resistivity  $\Gamma_D$  value is different from zero, part of the LDOS broadening should be ascribed to extrinsic factors such as finite noise temperature or presence of a contaminated surface layer.

In conclusion, we measured, by STS, neutron irradiated MgB<sub>2</sub> thin films grown by HPCVD. From tunnel spectra analysis we estimated the behavior of  $\Delta_{\pi}$  and  $\Gamma_{D}$ as a function of the introduced disorder. At low level of disorder (T<sub>c</sub> lowered from 40 to 36 K)  $\Delta_{\pi}$  increases slightly as an effect of interband scattering, in quantitative agreement with the two band theory. Furthermore, by comparing the behavior of the  $\Gamma_{D}$  parameter with resistivity we were also able to discuss the scattering mechanisms and reasonably infer the role of the interband scattering in determining the broadening of the measured density of states.
